PRELIMINARY DESIGN OF A
HIGH TEMPERATURE
SOLAR BRAYTON SPACE POWER SYSTEM

George R. Whittinghill

February 1983

SSL#7-83

(Under NASA Grant NAGW-21)

ABSTRACT

A high temperature solar Brayton power system was designed for a continuous output of 90 KWe in low earth orbit. The energy is stored in the heat of fusion of silicon. The system was optimized for minimum specific mass. High technology materials are used to lighten structural elements where applicable. Without gimbaling to decouple the power section from a space platform, the system optimizes at 28.5 KG/KWe with a cycle efficiency of 25 %. This represents a 3.5 times reduction in mass as compared to equivalent power solar cell/ battery combinations with a threefold increase in system efficiency.

ACKNOWLEDGEMENTS

This work was made possible by a NASA grant, NAGW-21.

My sincere appreciation goes to Professor Manuel Martinez-Sanchez for all his help. Thanks are also due to Professor René Miller and those of the Space Systems Laboratory who assisted in the production of this report.

Ch 1. Introduction

In the next ten to fifteen years NASA plans to loft a space platform into low earth orbit, a type of modular space station easily configurable to accommodate almost any mission requirement. With such versatility, a scheduled power demand of 90 KWe (continuous) seems reasonable. The various options are nuclear thermionic, nuclear dynamic, solar electric and solar thermal. In the first analysis, the nuclear systems offer tremendous mission flexibility. Almost any power level can be accommodated, in a fairly compact size. The advantage of compactness should not be overlooked, because any object in low earth orbit suffers from orbit decay due to atmospheric drag. The amount of fuel used during a mission lifetime will be directly proportional to the projected area of the satellite. The smaller the satellite, the less the resupply costs become. Unfortunately, any advantage gained here is overshadowed by the characteristic large mass, a sizable fraction of which is the shielding necessary to man rate the system. Various designs have attempted to reduce this shielding mass by employing partial shields, which impose operating constraints on any areas outside the protected zones. Although this could be made to work, there is doubt that such a system would ever be man rated for a manned platform, where considerable extra vehicular activity is expected.

One other option is a solar cell / battery combination, the latter necessary for operation during earth shadow.

Within this power grouping, there are different technologies available for both the solar cells and the storage medium. Unfortunately, such systems suffer from low efficiency (typically 8 to 10 percent) and therefore present large areas for any power level. Drag makeup is then a problem. In addition, solar cells are limited in life to 6 or 7 years from electron and high energy proton damage, unavoidable consequences of either polar or high altitude orbits. Although the sun pointing requirement is not severe, the attitude control of large arrays is complicated by their high moments of inertia and by their lack of rigidity. However, these systems have logged more flight hours than any other and have the advantage of a very low technological risk. Their ideal application seems to lie with low power systems that operate in benign environments.

Solar thermal systems seem to offer an ideal solution for the projected power levels of a space platform. In the first analysis, they offer at least a 3.5 times decrease in system mass as compared to an equivalent solar electric system, with a threefold increase in system efficiency. This efficiency translates directly to threefold decrease in projected area for the same power output. Within the category of solar thermal systems, the choice of a specific thermodynamic cycle (Brayton, Rankine or Sterling) will affect the performance and specific mass (KG/KWe) of the power system. Of those mentioned, the author chose to investigate in some detail the Brayton cycle, as it responded most favorably to technological improvements with the least amount of

FIGURE 1. AN EARLY VERSION OF THE SOC WITH
TWO SOLAR BRAYTON POWER MODULES [5]

FIGURE 2. EXPLODED VIEW OF A BRAYTON RECEIVER [1]

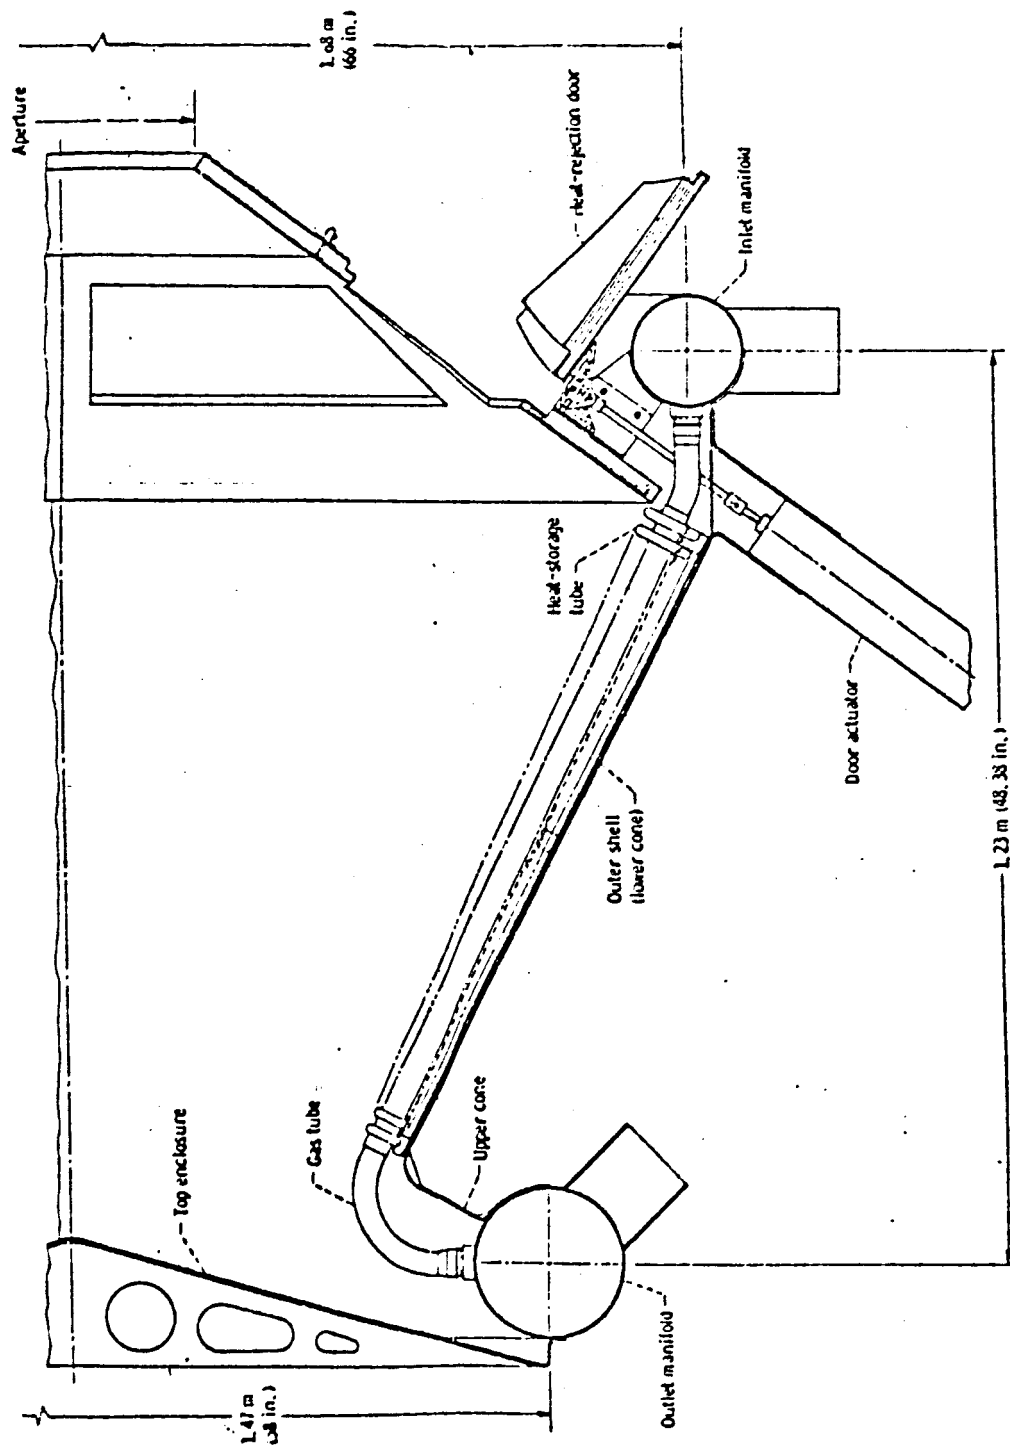

FIGURE 3. RECEIVER SECTION SHOWING HEAT STORAGE TUBE DETAIL [1]

uncertainty.

The design goal of any of these power systems is to meet the requirements with a minimum of cost. Since all of these systems would have to be boosted into low earth orbit, mass becomes the critical variable. Therefore this study optimized a particular Brayton cycle for maximum power and minimum mass. The resultant is not what one could achieve on earth where maximum efficiency probably would be more appropriate.

Figure 1 is an illustration taken from a MDAC study [05] of a space power system. Two redundant power units are connected via a gimbal to the rest of the structure. Each unit is comprised of a collector, a receiver, a rotating group of machinery, heat exchangers and waste heat radiators. The receiver, heat exchangers and the rotating group all are contained in the cylinder at the prime focus of the collector. The rotating group consists of a single stage centrifugal compressor, a single pole pair alternator and a single stage centrifugal turbine, all mounted on a common shaft. The working fluid in the cycle is a mixture of helium and xenon, which are noble gasses, combined to achieve a molecular weight of 40 g / mole. The mixture is inert to eliminate any potential oxidation problems.

An exploded view of the receiver is depicted in figure 2, illustrating the arrangement of tubes through which the working fluid circulates. Figure 3 shows one of these tubes in a little more detail, jacketed by a quantity of lithium flouride contained by another tube. The LiF serves as a heat

storage medium during orbital shadow periods. As the satellite enters the earth shadow, all of the LiF is molten. During the transit time, this LiF gradually freezes, releasing the energy contained in the latent heat of fusion (1046 kJ/kg at 1121 K). At shadow exit, all of the LiF is frozen, and slowly starts to melt as sunlight enters the cavity. Figure 5 plots the heats of fusion vs. melting temperatures of other possible storage mediums.

The salient design feature of this system is the large temperature difference available across the cycle. This has been made possible largely by the development of advanced materials. Carbon/carbon composite turbines have been built and tested to 2200 K and 720 m/s rim speeds [12]. Silicon carbide, which melts at 3100 K [06] can easily serve as a high temperature structure. Additionally, it is considerably less dense than the refractory metals it replaces, saving mass. Materials compatibility constraints in the radiators force the minimum cycle operating temperature to 350 K. The effective temperature of the radiator is 470 K, which results in a small area (59 m²). It is constructed of molybdenum and circulates a coolant mixture of potassium and sodium.

The next chapter models the thermodynamics of a regenerated Brayton cycle. These mathematical models are coded into a program that optimizes various parameters to minimize the system specific power.

The subsequent chapters take a closer look at the collection system performance, the turbomachinery and the radiator design. The radiator design itself is a complicated

optimization that finds a particular configuration that minimizes its contribution to system mass.

The last chapters present the results of this study, along with a sensitivity analysis of the assumed component efficiencies and scaling constants. Finally, some conclusions are drawn and recommendations made based on the research of this topic.

Ch. 2 Regenerative Brayton Cycle Analysis.

The goal here is to quantify primary cycle performance in terms of two basic variables. The first is the ratio of maximum to minimum cycle temperature, θ_c ; the second is the compressor pressure ratio, π_c . These primary variables will be traded against each other to find a system configuration that will maximize the power output for a given mass. The design electrical power is 90 Kw. Other secondary variables such as compressor efficiency η_c , turbine efficiency η_t , regenerator and heat exchanger effectiveness ϵ_1 , ϵ_2 and system pressure drops π_s will then be varied within reasonable bounds for a sensitivity analysis. The initial mass estimates are taken from a MDAC report [05].

The quantity that is minimized is the sum of all of the individual contributions to the system mass: collector, heat storage, regeneration and radiator masses. The turbomachinery itself was considered negligible in the first analysis. Therefore,

$$\frac{M_{tot}}{P_e} = \frac{M_{coll}}{P_e} + \frac{M_{sto}}{P_e} + \frac{M_{reg}}{P_e} + \frac{M_{rad}}{P_e}$$

All of these terms are functions of cycle efficiency, so that will be derived first. Consider the schematic and T-S diagrams illustrated in figure 4.

We can start by defining the compressor temperature ratio, τ_c (T_1/T_0) and the turbine temperature ratio, τ_t (T_4/T_m) in terms of the compressor pressure ratio, namely

Figure 4. Brayton Cycle Schematic

$$\zeta_c = 1 - \frac{\pi_c^{\gamma/\gamma_s} - 1}{\eta_c} \quad \zeta_c = 1 - \eta_c \left[1 - \left(\frac{1}{\pi_c \pi_s} \right)^{\gamma/\gamma_s} \right]$$

where γ is the ratio of specific heats (5/3) of the working fluid. The thermal efficiency is defined as the power extracted over the amount of heat inputted. The extracted power is the fraction of the turbine power that the compressor does not use. The heat input is the power added to the working fluid to take it from T_1 to T_m . For low pressure ratio cycles, the turbine exit temperature is considerably higher than the compressor discharge temperature. The regenerator takes that temperature differential and transfers it to the compressor output stream, thereby reducing the necessary heat input to accomplish the same work. The cycle then becomes more efficient. As the cycle pressure ratio increases, the benefit of regeneration diminishes, and can ultimately become a detriment ($T_1 > T_4$).

Unfortunately, this transfer of heat is not ideal, and is limited by the heat exchanger effectiveness. It is defined as the actual temperature difference over the available temperature difference. The regenerator and waste heat exchanger effectivenesses become

$$\epsilon_1 = \frac{T_2 - T_1}{T_4 - T_1} \quad \epsilon_2 = \frac{T_8 - T_7}{T_5 - T_7}$$

The shaft power becomes

$$P_s = \dot{m} C_p T_m (1 - \mathcal{Z}_c) - \dot{m} C_p T_o (\mathcal{Z}_c - 1)$$

$$\frac{P_s}{\dot{m} C_p T_o} = W = \theta_t (1 - \mathcal{Z}_c) - \mathcal{Z}_c + 1$$

The electrical power is simply the shaft power times the alternator efficiency. As mentioned before, thermal efficiency is the ratio of the power extracted over the amount of heat added. However, the heat that the cycle sees has been collected by the mirror and transferred to the working fluid through the heat storage medium. Therefore the cycle efficiency becomes

$$\eta_{cy} = \frac{P_e}{Q_{in}} = \eta_{coll} \eta_{sto} \frac{\dot{m} C_p T_o W}{\dot{m} C_p (T_m - T_2)} \eta_{alt}$$

Then from the definition of regenerator effectiveness,

$$T_2 = T_1 + \epsilon_r (T_4 - T_1)$$

$$\frac{T_2}{T_o} = \mathcal{Z}_c + \epsilon_r (\theta_t \mathcal{Z}_c - \mathcal{Z}_c)$$

And the cycle efficiency becomes

$$\eta_{cy} = \eta_{coll} \eta_{sto} \frac{\theta_t (1 - \mathcal{Z}_c) - \mathcal{Z}_c + 1}{\theta_t - \mathcal{Z}_c - \epsilon_r (\theta_t \mathcal{Z}_c - \mathcal{Z}_c)}$$

It is useful at this point to introduce a scaling variable μ , which represents the mass per unit area of that

particular component. Proceeding with the collection system one can see that the area required to deliver a certain power is the ratio of electrical power over the product of the cycle efficiency and the solar constant (S) at 1AU.

$$M_{coll} = \mu_{coll} A_{coll} = \mu_{coll} \frac{P_e}{S \eta_{cy}}$$

However, since there is a heat storage medium, the collector has to be oversized so that during insolation, it is providing enough heat to drive the cycle and liquify the heat storage substance. The heat is stored in the substances' latent heat of fusion. Therefore the collector is oversized by the ratio of the systems' time in shadow over the product of the time in sunlight and storage efficiency.

$$\frac{M_{coll}}{P_e} = \frac{\mu_{coll}}{S \eta_{cy}} \left(1 + \frac{t_{sh}}{t_{sun} \eta_{stb}} \right)$$

One might note that the collector efficiency is a strong function of the surface quality of the mirror. Unfortunately due to its large size (24 m dia), it has to be constructed in segments (akin to those in an umbrella) and assembled by EVA. This process will have an unknown impact on collection system performance. Chapter 3 models the reflector physics and determines the effect of mirror surface quality, mirror rim angle, cavity temperature and aperture size on collection

efficiency.

Next, we come to the heat storage medium. The literature suggests that at no time will the space platform be eclipsed for more than 36 minutes in LEO. Any heat storage medium will have to provide enough power during that period to insure steady state operation. The medium should be sized so that at the start of the eclipse the substance is completely liquid, gradually freezing and releasing heat at its melting point. The substance chosen needs to be compatible with its containment vessel (no corrosion), needs a melting point slightly higher than the maximum cycle temperature and a high heat of fusion.

A plot of the viable candidates is shown in figure 5. Of these, silicon seems best with a melting point at 1685 K and a heat of fusion of 1787 kJ/kg. Then the mass per unit power becomes

$$\frac{M_{sto}}{P_e} = (1 + F_{sto}) \frac{t_{sh}}{\eta_{cy} h_f}$$

where F_{sto} is the fraction of the storage mass needed to contain it. This includes the tube structure, the insulation, the aperture and cavity control devices and the receiver walls. This constant was chosen to be 120 percent after [06].

The next item of interest is the regenerator specific mass. If α_{reg} is the regenerator scaling variable (KG/KWt), then from the T-S diagram in figure 4, one can see that the regenerator mass is

Figure 5. Heats of fusion vs. melting temperature for various substances. [6]

$$M_{reg} = \lambda_{reg} \dot{m} C_p (T_2 - T_1) = \lambda_r \dot{m} C_p T_m \xi \left(\tau_c - \frac{\tau_c}{\theta_c} \right)$$

Also, from the cycle efficiency calculation, the electrical power can be written as

$$P_e = \eta_{alt} \dot{m} C_p T_m \left(1 - \tau_c - \frac{\tau_c - 1}{\theta_c} \right)$$

Then the mass per unit power for the regenerator becomes

$$\frac{M_{reg}}{P_e} = \lambda_r \xi \left\{ \frac{\tau_c - \frac{\tau_c}{\theta_c}}{1 - \tau_c - \frac{\tau_c - 1}{\theta_c}} \right\}$$

The last item to consider is the radiator, the purpose of which is to dispose of nonusable heat. Careful attention needs to be paid to the design, as the bottom cycle temperature is a very strong driver of the physical size and mass. For the same useful power output, the higher the cycle temperature is pushed, the smaller the radiator becomes. So the size is set by the dissipation requirement, maximum cycle temperature, cycle efficiency and material choice.

For the purposes of the cycle optimization, a simplified model of a fin and tube design will be considered. Although chapter 5 presents the mathematical models to design the radiator, the program that incorporated these models took too long to execute, and proved impractical to use as a subroutine in the larger cycle optimization.

For these purposes, only T_7 and T_8 are of interest. They are related to the main cycle temperatures through the heat exchanger effectivenesses, ϵ_1 and ϵ_2 .

$$T_7 = \left(1 - \epsilon_1 - \frac{\epsilon_1 - 1}{\epsilon_2}\right) T_4 + \epsilon_1 \left(1 - \frac{1}{\epsilon_2}\right) T_1 + \frac{1}{\epsilon_2} T_0$$

$$T_8 = \left(2 + \epsilon_1 \left(\frac{1}{\epsilon_2} - 2\right) - \frac{1}{\epsilon_2}\right) T_4 + \left(2\epsilon_1 - \frac{\epsilon_1}{\epsilon_2}\right) T_1 + \left(\frac{1}{\epsilon_2} - 1\right) T_0$$

These, in turn can be written in terms of known cycle quantities.

$$\theta_7 = \frac{T_7}{T_m} = \left(1 - \epsilon_1 + \frac{\epsilon_1 - 1}{\epsilon_2}\right) \theta_t + \epsilon_1 \left(1 - \frac{1}{\epsilon_2}\right) \frac{\theta_c}{\theta_t} + \frac{1}{\epsilon_2} \frac{1}{\theta_t}$$

$$\theta_8 = \frac{T_8}{T_m} = \left(2 + \epsilon_1 \left(\frac{1}{\epsilon_2} - 2\right) - \frac{1}{\epsilon_2}\right) \theta_t + \left(2\epsilon_1 - \frac{\epsilon_1}{\epsilon_2}\right) \frac{\theta_c}{\theta_t} + \left(\frac{1}{\epsilon_2} - 1\right) \frac{1}{\theta_t}$$

An order of magnitude sizing would proceed as follows. Consider an incremental radiator section, pictured below.

An incremental amount of heat convected out of the working fluid is

$$dQ = \dot{m} C_p dT$$

Similarly, an incremental amount of heat radiated away (with no background radiation) is

$$dQ = -2 \epsilon \sigma T^4 dA$$

Equating the two and integrating, one obtains for the area of the radiator divided by the product of the mass flow and the coolant specific heat

$$\frac{A_r}{\dot{m} C_p} = \frac{1}{6 \epsilon \sigma} \left(\frac{1}{T_{out}^3} - \frac{1}{T_{in}^3} \right)$$

where A_r is the ideal radiator area divided by the fin efficiency. The radiated power, Q_r is

$$Q_r = \dot{m} C_p (T_{in} - T_{out}) = P_e \left(\frac{1 - \eta_{th}}{\eta_{th}} \right)$$

Finally, the expression for radiator specific mass becomes

$$\frac{M_{rad}}{P_e} = \mu_{rad} \frac{1}{6 \epsilon \sigma T_m^4 \eta_{fin}} \frac{1 - \eta_{th}}{\eta_{th}} \left(\frac{1/T_2^3 - 1/T_3^3}{T_3 - T_2} \right)$$

This last expression is a good estimate of the radiator specific mass. The scaling constant was adjusted to match those results obtained in chapter 5 to preserve accuracy in the optimization. The models used in chapter 5 included the effects of an earth background radiation temperature of 270 degrees K.

All of the terms developed in the preceeding pages were coded into the program listed in the back pages of this chapter. The results from the optimization are discussed in

2.2 Working Fluid Molecular Weight

The choice of the working fluid molecular weight is again made with component masses in mind. The most sensitive parameter is the regenerator surface area, where working fluid to working fluid heat transfer is required. The number of turbomachinery stages required for a certain pressure ratio is also a function of the gas molecular weight with an attendant impact on turbomachinery complexity and mass. Similarly the aerodynamic efficiencies of the compressor and turbine will be affected. This last consideration will impact the cycle thermal efficiency and the waste heat load. Within the range of mixtures to choose from, inert gasses are employed to eliminate any potential contaminants from the turbomachinery. The turbine is made out of a carbon/carbon composite and might be sensitive to high temperature reactions.

Helium is a good choice because of its high thermal conductivity which is a driver for small heat exchanger surface areas. It unfortunately also has a high specific heat which, for a given pressure rise (or drop) tends to push a design towards an increasing number of stages. This is the primary trade-off. The solution to this problem is a mixture of He with some other inert gas. Neon, argon, krypton and xenon are all viable possibilities, but only mixtures of He and Xe result in minimal increases (from pure He) in heat

Figure 6. Effects of working fluid molecular weight on relative heat exchanger area and gas thermal conductivity [7]

exchanger area, since the thermal conductivity (for a given molecular weight) remains the highest of all of the mixes (see figure 6). As mentioned earlier, pushing the molecular weight of the mixture will increase the aerodynamic blade efficiencies in a component. This stems from an increased volumetric flow, an increase in blade height, which in turn reduces the endwall losses and thereby increases the stage efficiency.

Chapter 3 Collector Performance

3.1 Collector configuration

The collector of this system measures approximately 12 m in radius. Since the driving factor in making this system competitive is the high power to mass ratio, deployable configurations of the mirror were not considered. The actuating mechanisms would be eliminated, making EVA assembly mandatory. Prefabricated petals, or segments of the mirror would be carefully assembled, resulting in a better quality reflector than might otherwise be possible. Still the author felt it was necessary to study the effects of an imperfect mirror, to see what impact various errors might have on collector performance or system weight. In the first analysis, any misorientation more than half of the sun's projected angle would render the system completely useless. Fortunately, Kaykaty [13,14] has spent some time investigating this problem, and has identified 4 important variables to optimize collector efficiency. These are surface error, mirror rim angle, orientation error and receiver cavity temperature. His calculations were compared with a more accurate simulation given in ref[13] and the results did not differ by more than 1.5%. Unfortunately, no comparisons were available with actual hardware. That notwithstanding, his methods were duplicated, albeit with some modifications.

When considering a collector system, two configurations

come immediately to mind. The simplest is the single reflector, focusing all of the energy at the focal point, which would be the receiver aperture. The other would also consist of a parabolic reflector, but augmented by a secondary reflector, hyperbolic in shape, to bring the focal point behind the primary mirror. (See figure 07). From the structural dynamics viewpoint, the latter is best: all large masses (receiver, radiators and primary reflector) are concentrated in a single area. Low frequency vibrations caused by Shuttles or OTV's docking with the space station would have a minimal effect on optical alignment. Unfortunately, optical quality will be worse since there are two reflectors and second surface longevity would be a problem. This is due primarily to some pretty severe temperature cycling during an orbital period. All of the primary surface's energy is getting reflected by the second surface, which would absorb some of the energy and reach a high equilibrium temperature before cooling off in the earth shadow. Additionally, it is uncertain whether the blockage due to the radiators and receiver would be any greater than that of the secondary reflector. In light of these factors the simple single reflector system was chosen.

A quick scan of figure 07 will show that approximately half of the energy dissipated by the radiators will sink into the primary reflector. So to check on steady state dish temperatures for both configurations, we can write an energy balance and solve for the temperature

Prime focus

Cassegrain focus

Figure 7 . Two Solar Brayton Power System configurations

$$Pr = Pa + Pd$$

[C01]

where: Pr is the radiated power

Pa is the solar absorbed power

Pd is the radiator dissipated power.

For the single reflector,

$$2 \pi R_m^2 \sigma \epsilon_p T^4 = \pi R_m^2 K a + a \frac{90 \text{ KWe}}{2} \frac{1 - N_{th}}{N_{th}} \quad [C02]$$

The nomenclature contains the variable names and meanings.

Solving for T

$$T^4 = \frac{K a}{2 \sigma \epsilon_m} + \frac{90 \text{ KWe}}{4 \pi R_m^2 \sigma \epsilon_m} \frac{a}{N_{th}} \frac{1 - N_{th}}{N_{th}} \quad [C03]$$

For silver coated fused silica with an overcoat of vapor deposited Inconel, $a = .05$ and $\epsilon_m = .80$. Assuming a cycle efficiency of 25%, (conservative for this system) then the steady state temperature reaches 194 degrees K. The thermal transients during an orbital period are found by solving

$$Q_{in} - Q_{out} = m C_p \frac{dT}{dt} \quad [C04]$$

Since this power system produces energy continually during an orbit, the radiators will dissipate the same power in the

shade as in the sun. There is also earth background infrared radiation to consider, but it will be ignored for a maximum transient analysis. So this results in a non linear equation of the form

$$\frac{dT}{dt} = \frac{1}{a} \left[\frac{90 \text{ KWe}}{2} - \frac{1 - N_{th}}{N_{th}} - \frac{1}{m C_p} - \frac{2 \pi R_m^2 \sigma \epsilon_m T^4}{m C_p} \right] \quad [C05]$$

The presence of the radiator power makes the equation difficult to solve analytically, so a Runge Kutta method was used to solve for $T(t)$. A good figure for collector mass is 2.1 kg/m^2 . And $C_p(\text{Al}) = 896 \text{ J/(kg K)}$. Low earth orbit dictates a maximum shadow time of 38 min., and so substituting all the relevant variables gives a value for the minimum temperature of the dish equal to 139 degrees K. So thermal transients remain reasonable at 55 degrees K. Repeating this calculation for the secondary mirror (radius = 1 m) of the Cassegrain arrangement, one finds that the steady state temperature is 673 degrees K and that the temperature at shadow exit is 392 degrees K. This gradient is more serious at 281 degrees, grounds enough to justify a single reflector system.

One other phenomenon that will affect collector life was recently observed on STS 4. An experiment was conducted to see if there was any material erosion in LEO, due to free oxygen impacting at orbital velocities, thereby oxidizing the surface. Polished surfaces were exposed in different directions to the flight velocity vector to quantify the effect.

Assuming the material being eroded is aluminium, an erosion rate of up to 40 microns per day was calculated at an orbital altitude of 241 kms. At 420 kms, this rate went down by 2 orders of magnitude. Either way, a mirror whose design life is supposed to be ten years would never last. Solar cells are typically protected with a thin (0.15 mm) coating of quartz. A similar coating might have to be applied at a penalty of about 0.4 kg/m^2 .

3.2 The effect of imperfections

The analysis in [13] is outlined as follows. Given the geometry shown in figure 08, it is clear that any errors (misalignment or statistical) will diffuse the energy over a larger area in the focal plane. Additionally, the sun is not a point source, so the image at the focus will have a finite size, depending on the mirror's optical geometry. Any aperture located in the focal plane will have to capture as much energy as possible while limiting the amount of re-radiation coming out of the cavity. The latter is driven primarily by the operating temperature of the receiver to the forth power and directly as the aperture area.

The thermodynamic cycle efficiencies will dictate the amount of power needed in the cavity, which in turn is a function of the mirror radius and achievable collection efficiency. Since scaling relationships between mirror mass and surface quality aren't readily available, the intent of this analysis is to determine a maximum acceptable error

Figure 8. The mirror and associated optics

before collector mass penalties become too great.

As mentioned before, Kaykaty determined that the two key geometrical variables are the mirror radius R_m and the rim angle T_m . These combine to form an expression for the focal length, F

$$F = \frac{R_m (1 + \cos(T_m))}{2 \sin(T_m)} \quad [C06]$$

The equation for a parabola with its origin at the focus is

$$\rho = \frac{2 F}{1 + \cos(T)} \quad [C07]$$

where ρ is the distance from the focus to any point on the surface and T measures the angular position of that point. Restricting the analysis for the present to the perfect mirror, it is clear by referring to figure 08 that if a reflected image of the sun from any point on the surface is viewed normal to the image path, that image will form a circle. At the focal plane, this same image will form an ellipse whose semi-major axis is a function of T . If α is defined as the half angle of the sun at 1 AU then the axes are given by

$$b = \rho \tan(\alpha) \quad [C08]$$
$$a = \frac{\rho \tan(\alpha)}{\cos(T)}$$

It makes sense then that the higher the rim angle of the collector, the more diffuse the image will be in the focal plane. As one rotates around the optical axis with a constant T , the image formed at the focal plane will consist of a set of superimposed ellipses all with their origins at the focus. If K is the solar constant, the amount of energy that this swept ring intercepts is simply

$$E_e = K 2 \pi R_e dR_e \quad [C09]$$

In polar coordinates

$$R_e = \rho \sin(T)$$

$$dR_e = \rho \cos(T) dT + \sin(T) d(\rho) \quad [C10]$$

$$d(\rho) = \frac{\rho \sin(T) dT}{1 + \cos(T)}$$

Upon substitution, eqn[C10] becomes

$$\begin{aligned} dR_e &= \rho \cos(T) dT + \frac{\rho \sin^2(T) dT}{1 + \cos(T)} \\ &= \rho dT \end{aligned} \quad [C11]$$

Substitution into [C09] gives

$$E_e = 2 \pi K \rho \sin^2(T) dT \quad [C14]$$

Integrated from $T=0$ to T_m this last expression should equal the mirror's projected area times K .

Now since the optimum aperture radius is smaller than the

largest of the ellipses axes, not all of the reflected energy is going into the receiver. The presence of any errors will scatter the reflected energy even more over the focal plane, by displacing the centers of the ellipses away from the focal point. The two kinds of errors considered are the statistical surface errors and misorientation error. The surface errors exist as manufacturing imperfections, assumed to follow a normal distribution of 0 mean and some specified standard deviation. As data points, NASA Lewis built a 6.1 m (20 ft) diameter Mg mirror to a 1 sigma value of 1 mrad which massed at 5 kg/m² and later, TRW constructed a 0.9 m (3 ft) diameter mirror to 0.3 mrad at 1.3 kg/m². For this analysis, the author believes that a 24 m (79 ft) diameter mirror could be built to 1 mrad at 2.1 kg/m².

Reference [13] displaced the ellipses only radially away from the focal point, which results in a symmetrical energy distribution around the focal point. This simplifies the analysis, but results in a slightly optimistic level of performance. Consult figure 09. This treatment also makes the analysis of a misoriented system easier as will be discussed. This displacement distance is given by

$$k = \frac{\rho \tan(2 e)}{\cos(T)}$$

where e is the average error of a narrow band within the statistical distribution of errors.

Now the task at hand is to determine what fraction of a given

Image superposition in focal plane
for a perfect mirror

Image superposition in focal plane
for an imperfect mirror

FIGURE 9.

ellipse's area is coincident with the aperture. The simplest way to do this is to perform an integration from 0 to the aperture radius of circular elements that lie within the domain of the ellipses. Several configurations of circular elements and ellipses are possible. Consult figure 10. The progression outlined by cases 1-4 represents different criteria for computing $\int r$, the arclength of a circular element common to the circle and the ellipse as one integrates dr from 0 to the aperture radius.

Case 1 holds when the circle lies within the domain of the ellipse. Figuring exactly when this is the case is easier to do when the equation of the ellipse is recast in polar coordinates

$$\left(\frac{x - k}{a} \right)^2 + \left(\frac{y}{b} \right)^2 = 1$$

$$\text{let } x = r \cos(T) \quad y = r \sin(T)$$

$$s = \left(\frac{a}{b} \right)^2 \quad q = \left(\frac{a}{b} \right)^2 - \left(\frac{k}{b} \right)^2$$

Then solving for r , one obtains

$$r = \frac{k \cos(T) + a \sqrt{q + \cos^2(T) (1 - q)}}{s + (1 - s) \cos^2(T)} \quad [C13]$$

There are really two solutions for r , + and -, the latter having no physical meaning. Taking the derivative of r wrt T will lead a minimum of r and where it is located. Refer to

CASE 1

CASE 1A

CASE 2

FIGURE 10

CASE 3

CASE 4

FIGURE 10 (cont.)

figure 10.

$$\frac{dr}{dT} = \frac{-\sin(T)}{[s \sin^2(T) + \cos^2(T)]^{3/2}} \quad [C14]$$

$$\begin{aligned} & \left(\frac{a \cos(T) (1-q)}{\sqrt{q + \cos^2(T) (1-q)}} + k \right) (s + (1-s) \cos^2(T)) \\ & - 2 \cos(T) (1-s) (k \cos(T) + a \sqrt{q + \cos^2(T) (1-q)}) \end{aligned}$$

Finding the T's for dr/dT to be zero is not easily accomplished analytically, hence a numerical scheme such as the secant method has to be used. Once the correct solution is found, reinserting T into eqn C13 will yield the maximum radius for a circle to be completely inside the ellipse. Hence the value of the arclength will be

$$S = 2 \pi r$$

Case 1a exists when the ellipse starts out beyond the reach of r. The test for this case is when $r < (k-a)$. And the arclength is simply zero.

Case 2 needs to be treated a bit differently, since X_i/π is less than 1 and is a function of geometry. This situation holds when $r < \text{abs}(k-a)$ and when $r < k+a$. Here it is convenient to solve for the coordinates of the intersection of the circle and ellipse. Given their well known formulas,

$$y^2 = r^2 - x^2 \quad \text{and} \quad y^2 = b^2 - \left(\frac{b}{a}\right)^2 (x - k)^2$$

and setting them equal to each other results in an equation for x

$$x = \frac{-kb + \sqrt{b^2 k^2 - (a^2 - b^2)(ab - bk - ar)}}{a - b} \quad [C15]$$

Note that the result is different than the one presented in [1]. There are two solutions as expected.

[C16]

$$Xi_1 = \cos\left(\frac{-1 \cdot x_1}{r}\right) \quad Xi_2 = \cos\left(\frac{-1 \cdot x_2}{r}\right)$$

Therefore the swept arclength that lies within the ellipse is

$$S = 2r (Xi_1 + Xi_2)$$

Case 3 is similar to case 2 save that only one solution of x is valid. This case is treated when $r > \text{abs}(k-a)$ and $r < k+a$. The negative value of x is simply discarded. Then the arclength becomes

$$S = 2r \cos\left(\frac{-1 \cdot x}{r}\right)$$

Case 4 is the simplest. If $r > (k+a)$ then S is zero.

After the arclength has been found for a particular

configuration, the following yields the fraction of the ellipse's area that has entered the aperture

$$\frac{1}{\pi a b} \int_0^{Ra} S dr \quad [C17]$$

Combining the relevant equations [C11, C17] to come up with the total power in the aperture yields

$$P_{ap} = 2 \pi K \int_{T_0}^{T_m} \left(\frac{1}{\pi a b} \int_0^{Ra} S dr \right) \rho \sin^2(T) dT \quad [C18]$$

where T_0 has been changed from 0 to account for the receiver blockage. The energy efficiency of a particular configuration would be the power going in the aperture divided by the amount of energy being intercepted by the dish.

$$\eta_e = \frac{2}{\pi R_m^2} \int_{T_0}^{T_m} \left(\frac{1}{a b} \int_0^{Ra} S dr \right) \rho \sin^2(T) dT \quad [C19]$$

Misorientation error, which can be thought of as either power system misalignment with the sun or mirror-receiver misalignment, will spread out to an even greater degree the energy in the focal plane. The equation above needs to be modified slightly to account for the effective shift in aperture location. If d quantifies this shift, the interior equation in [C22] changes to

$$\frac{1}{a b} \int_0^{Ra+d} \frac{\phi}{\pi} S dr$$

Figure 11. Misaligned aperture geometries in the focal plane.

provided that the energy distribution remains symmetrical about the origin. The shift distance (check figure 11) is quantified by

$$d = F \tan(m) \quad [C20]$$

For small angles of misorientation, the ellipse displacement k , need not be modified. The ratio ϕ/π is found by solving for the intersecting points of the periphery of the aperture and an arbitrary circle of radius r

$$x^2 + y^2 = r^2 \quad (x + d)^2 + y^2 = r^2$$

Equating y 's and solving for x and ϕ

$$x = \frac{Ra^2 - r^2}{2d} - \frac{d}{2} \quad [C21]$$

$$\phi = \cos^{-1} \left(\frac{x}{r} \right)$$

So once again the energy efficiency with error modeling becomes

$$Ne = \frac{2}{\pi R_m^2} \int_{T_0}^{T_m} \left(\frac{1}{a b} \int_0^{Ra d} \frac{\phi}{\pi} S dr \right) \rho \sin(T) dT \quad [C22]$$

The concentration efficiency is a product of the blockage

efficiency, mirror coating efficiency energy efficiency and the effective solar absorptivity of the receiver. However, the receiver can be thought of as a blackbody, so the absorptivity is set to 1. To get the collection efficiency, one needs to include the radiation losses out the aperture. These are

$$L_r = \frac{\epsilon_m \sigma A_{ap} T_r^4}{\pi R_m^2 K} \quad [C23]$$

So the overall collection efficiency becomes

$$N_c = N_b N_r N_e - L_r \quad [C24]$$

One needs to remember that this efficiency is solely a function of one error e , and one misorientation angle, m . As mentioned before the surface errors behave in a normally distributed manner. So, picking a certain standard deviation, one proceeds to divide up the mirror into specific error bands, each having a certain probability of existing. Then the computation for N_e is run for each error band's average e and for 5 or 6 different aperture to mirror radius ratios. A table can be constructed with all these values, as exemplified in tables 1 - 15. Next all the energy efficiencies common to a certain radius ratio are multiplied by their probability of occurrence and then summed. The results of these summations can be plotted for clarity. If the radiation

these summations can be plotted for clarity. If the radiation losses are subtracted from these curves, then an optimum collection efficiency should appear at some specific aperture radius. All this computation is for one specific mirror geometry and cavity temperature. The latter is invariant at 1750 degrees K from the cycle analysis. The former is a matter of choice, insofar that the power constraints are satisfied. For a good first guess [16] presents a quick method to find the optimum mirror rim angle, provided that there are no errors, which works out to be 45 degrees.

3.3 Program Results

Figure 12 shows the sensitivity of collection efficiency as a function of misorientation for a given mirror geometry and surface quality. The data is represented in this fashion to show the impact of pointing accuracy on the collection system efficiency. One should notice that the higher the mirror rim angle, the less sensitive the collection efficiency is to variations in pointing accuracy, at the expense of some collection efficiency. A reasonable compromise would be to design the mirror with a rim angle of 55 degrees. Without additional knowledge of mirror quality vs mass, any cycle optimization algorithm will try and drive mirror surface error to 0. Therefore it must be fixed to some reasonable value, say $1 \text{ sigma} = 1 \text{ milliradian}$. Reference [17] has investigated the effects of higher surface errors and reports that collection efficiency drops to about 64% at 4

Figure 12a.

mmrad error and 40% at 8 mmrad error if the cavity temperature is held at 1800 degrees K. For a surface quality of 1 mmrad, one can achieve a collection efficiency of 81% with some tolerance for misalignment error. The optimum aperture radius to choose is then 14 cm.

Figure 12 b shows some of Kaykaty's work for the same collector. The effect of misaligning the mirror by half of the sun's projected angle at 1 AU (15 min) is clearly shown. The performance is penalized by about 6%. As a matter of interest, the space telescope can achieve sub second pointing accuracy. It is unreasonable to expect a space platform with shifting masses aboard to maintain that kind of accuracy. So the author felt that some misalignment error had to be included in the design stage.

Due in part to some differences in the equations, the author's computed values for η in aperture energy efficiency were somewhat larger (3%), but these differences weren't discernible when collection efficiency was found.

Figure 13. Energy and collection efficiency as a function of receiver aperture radius [13]

Chapter 4. Turbomachinery design

4.1 General considerations

To simplify the dynamics of the power station, the author has chosen a sun pointing system. This eliminates any problems of transmitting power through a gimbal. The design will revolve around a single rotating group consisting of a single stage centrifugal compressor and turbine and a single pole pair alternator all on a common shaft, much like the Garrett BRU's developed for NASA a decade ago (see figure 13). The problem of attitude control in the face of speed variations of the turbomachinery needs to be addressed.

Figure 14 is a good design chart for dimensioning the turbomachinery. The choices of specific speed, N_s , and specific diameter, D_s , (defined by equations 4 and 5) are endless, even within a desired efficiency range. To define the proper region of operation, one needs to consider the aerodynamic, stress and bearing limitations.

The bearing limitation encountered in most turbopumps does not apply here, since this configuration uses air-bearings with no mechanical contact between the shaft and foil bearing surface. Of more concern would be the labyrinth type seals on either end of the alternator. The working pressure differential across them is not severe, but the high temperatures on the turbine side might cause some concern.

A maximum of 610 m/s was imposed on the rotating components rim speed to avoid potential failures due to creep or root stress. Existing gas turbines operate with rim speeds

Figure 13. Garrett Brayton Rotating Unit

around 550 m/s, using high strength alloys. The material that should be used in this application is a carbon/carbon composite, whose strength increases with temperature. The physical properties of this layup and the construction details are classified, but calculations using unidirectional graphite/epoxy composites are valid, yet conservative. A typical density for a graphite/epoxy composite is 1525 kg/m. The yield stress is 1661 megaPascals. Considering only hoop stresses, one finds that

$$\sigma = \rho v^2$$

This results in a maximum rim speed of 1040 m/s before failure. Even with all of the conservative assumptions, there is a factor of safety of 1.7 for a rim speed of 610 m/s.

Fluid mechanics also imposes a minimum acceptable rim speed for the given enthalpy rise of 150 m/s, labelled "limit line for dynamic pumps" in figure 14. Between these constraints, there is a choice between the desired head rise and the obtainable efficiency, both subject to the specific heat (molecular weight) of the working fluid. The objective is to choose a mixture with a molecular weight that is as low as possible to improve the heat transfer effectiveness of the recuperator. The rationale for this is discussed in chapter 2.

4.2 Turbine design.

FIGURE 14 $N_s - D_s$ DIAGRAM FOR VARIOUS PUMPS

In most gas turbine applications, the turbine is the most highly stressed component of the rotating group, being subject to the highest temperatures and operating at the highest rim speed. As previously discussed, we are going to limit the latter to 610 m/s. With this in mind, one can proceed to find the geometrical properties of the impeller. One must start by computing the head loss required, defined by

$$gH = C_p T_{\max} (1 - Z_c) \quad [11]$$

where $C_p = (\gamma/\gamma-1) R/\mathcal{K}$. Right away, the choice of the molecular weight affects the design. Lowering the molecular weight increases the head loss and drives the stage efficiency towards lower values. The flow coefficient, γ , is defined as

$$\gamma = \frac{gH}{(\Omega R)^2} \quad [12]$$

where R is the rim speed. For reasons of flow stability, one would like to keep the value of γ less than unity. At unity, the flow passages along the impeller blades are perfectly radial while at values less than unity they become 'backwards leaning'. Additionally, if one operates in english units, the following expression relates specific speed to diameter by

$$NsDs = \frac{108.3}{\sqrt{\gamma}} \quad [3]$$

This relationship is plotted in figure 14 for $\gamma = 1$. This is the lower rim speed limit line. This means simply that $\gamma > 1$ is not acceptable. So one normally would pick an operating point in the region of highest efficiency to the right of the appropriate limit line. As mentioned earlier, however, one would like to choose a low molecular weight working fluid. If the rim speed is held constant, lowering the gas mixture molecular weight will increase the head rise [eq. 1] and the flow coefficient [eq 2], and reduce the product $Ns Ds$ [eq. 3]. Selecting too low a molecular weight would constrain the operating point to regions of poor efficiency (see figure 14). Table 16 presents the specific heats, head losses, flow coefficients and maximum achievable stage efficiencies as a function of gas mixture molecular weight. From this data, a molecular weight of 40 was selected. The attendant head loss is 271,000 J/kg and the flow coefficient is 0.728. Substituting the flow coefficient in equation 3 and picking a design point within the 90% efficiency contour gives

$$Ns = 2,400 \quad Ds = .053 \quad (\text{english units})$$

To calculate the geometry of the impeller disk, one needs to express the nondimensional specific speed and diameter in terms of physical properties, namely

TABLE 16

Turbine performance vs. working fluid molecular weight.

	M He - Xe molecular weight			
	20	40	60	80
C_p	1039.5	519.75	346.5	259.875
gH	542,000	271,000	180,670	135,500
ψ	1.457	0.728	0.486	0.364
η_{\max}	?	.90	.95	.95

$$Ns^* = \frac{\Omega Q^{1/2}}{(gH)^{3/4}} \quad \text{and} \quad Ds^* = \frac{D (gH)^{1/4}}{Q^{1/2}} \quad [4]$$

where Q and Ω are the volumetric flow rate and the rotational frequency. These non-dimensional groups are related to the english quantities by

$$Ns = 2,728 Ns^* \quad Ds = .01985 Ds^* \quad [5]$$

So in nondimensional units these values become

$$Ns^* = .879 \quad Ds^* = 2.67$$

Before proceeding, we need to select either Ω or D . For convenient electrical design, the author chooses to have a single pole pair alternator spinning at 800 rev/sec which gives 800 Hz at rated power. Therefore, the compressor, alternator and turbine will all spin at 48,000 rpm or 5026.6 rad/sec. This immediately fixes the radius of the impeller to 12.14 cm. The volumetric flow rate can be simply found from [4]

$$Q = \frac{(Ns^*)^2 (gH)^{3/2}}{\Omega^2} \quad [6]$$

and is equal to 4.314 m³/sec. Another way of writing [6] would be

$$Q = 2 \pi R b V_r \quad [7]$$

where R is the impeller radius, b is the flow passage width

at the rim and V_r is the (subsonic) radial gas velocity also at the rim. Tentatively selecting a mach number of .5 for the radial gas flow in the rotating frame, one can find V_r indirectly through energy conservation. Given

$$C_p T_m = C_p T + \frac{V_r^2}{2} \quad \text{and} \quad \frac{V_r}{\sqrt{\gamma R T}} = .5 \quad [8]$$

where T_m is the maximum turbine inlet temperature, one can solve for V_r yielding

$$V_r = \left[\frac{2 \gamma R T_m C_p}{8 C_p + \gamma R} \right]^{1/2} \quad [9]$$

Proper substitution of the appropriate values gives a radial gas velocity of 363 m/sec. Then from equations 4 and 7 one obtains the ratio of flow passage width to impeller radius from

$$\frac{b}{R} = \frac{2}{\pi} \frac{1}{V_r} \frac{(gH)^{1/2}}{(D^*)^2} \quad [10]$$

This final value is 0.128. The final geometry is sketched in figure 15, along with that of the compressor.

4.3 Compressor design

The compressor is sized in exactly the same fashion as the turbine. The head rise, in this case is

FIGURE 15 DIMENSIONS OF TURBINE AND COMPRESSOR IMPELLERS.

$$gH = C_p T_o (\hat{C}_c - 1)$$

[11]

The specific heat has already been determined and $\hat{C}_c = 1.714$ from the cycle analysis. Then the head rise is 143,192 J/kg. For convenience, if we choose the same non-dimensional specific speed and diameter for the compressor as the turbine, the rim speed can be found from

$$\frac{N_s}{D_s} = \frac{\Omega D}{(gH)^{1/2}} \quad [12]$$

and yields a value for $\Omega r = 444$ m/sec. The volumetric flow rate can then be found from equation 6, remembering that Q has the same value for all of the rotating components. Q then becomes 1.657 m³/sec. If one can assume that the impeller disks remain similar geometrically, then the ratio b/R stays the same at .128. The radial gas velocity then results from equation 10 and is equal to 264 m/sec. The temperature of the gas at the impeller rim can be found from equation 8 and is 319 K. The speed of sound at that point is 332 m/s. This implies that the radial gas flow in the rotating frame is at $M = 0.79$, which is a bit high for this application. Recasting the equation for b/R [10] in terms of Mach number

$$\frac{b}{R} = \frac{2}{\pi} \left[\frac{2 C_p + M^2 \gamma R}{2 M^2 \gamma R C_p T} \right] \frac{(gH)^{1/2}}{(D^*)^2} \quad [13]$$

Picking a radial gas Mach number of 0.6 (207.3 m/s) gives a value for b/R equal to 0.163. The Mach number in the diffuser then becomes

$$M_0 = \frac{\sqrt{\Omega r + V r}}{V^*} \quad [14]$$

The speed of sound at the rim is 345.5 m/s and the diffuser Mach number in the rest frame is 1.42. This allows us to ultimately calculate the cycle peak pressure. We know that

$$\rho = \frac{\dot{m}}{Q}$$

where \dot{m} is the mass flow through the cycle. With a gas molecular weight of 40, the mass flow works out to 0.7051 kg/sec, and the density becomes 0.4256 kg/m³. The compressible flow function for density is

$$\rho_{tot} = \rho \left(1 + \frac{\gamma - 1}{2} M_0^2 \right)^{1/(\gamma - 1)}$$

so that the flow stagnates ideally to a density of 0.92 kg/m³. Since the temperature at that point is 662 K, this gives a cycle peak pressure of

$$P = \gamma R_g T = 126,544 \text{ N/m}^2$$

This corresponds to 1.25 atmospheres, a very acceptable

value.

Ch. 5 Waste Heat Radiators

5.1 Perspective

Traditionally, the waste heat radiators of a Brayton cycle were the most massive components of the system. Thermodynamics dictate a non isothermal radiator design, which needs increasing area to radiate power as the temperature drops. Previous designs used organic coolants which could not operate much above 500 K. The effective temperature (that which would dissipate the required power if the radiator was isothermal) was then quite low. These two reasons were primarily responsible for the large masses of these designs. The key to this design is the high operating temperature. Intuitively, the lower the bottom cycle temperature, the more work is available from the system. Unfortunately, there is the background earth infra-red radiation to contend with, with an energy spectrum that corresponds to a blackbody radiating at 270 K. This effect cannot be ignored, since the energy that is being rejected by the cycle is right in that range. Therefore special coatings, etc. are useless. This then imposes a constraint or a maximum value on the cycle temperature ratio.

There are also material constraints, not only in the physical properties (melting, freezing points) of the coolant and in the choice of fin material, but of compatibility of the fin and tube material to the coolant. At radiator inlet temperatures of 675 K corrosion problems may be quite severe.

The combination of aluminium and mercury was ruled out for that reason. Additionally, the material chosen for the piping cannot soften at radiator inlet temperatures for both micrometeorite protection and internal pressure considerations. Judging from some strength vs. hours at temperature curves, the tube fin material has to have a melting point at least twice the maximum working temperature. In light of all these factors, molybdenum was chosen for the radiator material and potassium selected for the coolant. Potassium is a liquid metal which freezes at 337 K, so the minimum cycle temperature was raised to 350 K. Further thought must be given to the start up problem since potassium is frozen at room temperature. A 76.7 to 23.3 percent (by weight) mix of potassium and sodium will lower the freezing point of the mixture to 260 K, thereby resolving that problem. Figure R1 is a phase diagram of mixtures of NaK. For purposes of analysis though, only pure potassium was used.

Another matter worth considering is the reliability of the radiators. A leak in a liquid coolant fin and tube design would prove disastrous. A more reliable system would use a quantity of heat pipes, each independent of the other. Single point failure would then be eliminated, and repair could be carried out without powering down the whole system. A good simulation of the physics of such a system and some algorithm to optimize a given configuration was beyond the scope of this treatise. However, the analysis and optimization of the more conventional fin and tube radiator was a more reasonable task. It is generally accepted that the mass to power ratio

of a heat pipe radiator is less than its flow-type counterpart, so any estimates made with the latter should be conservative. Finally, since the radiator in this design is the least massive of the major components of the power cycle, any errors introduced by conservatism will be minimal.

5.2 Design Considerations

To account for some protection against micrometeorites, it is necessary to add material to the manifolding and the tubes for some reliability. The quantity added is a function of the desired time to perforation. The design life of this system is 10 years, so there is no need to protect the system against the 10,000 year impact. Ref[11] presents some fitted empirical data for micrometeorite impacts at near earth conditions. The reference gives certain formulas that relate perforation rate to skin thickness. These are plotted in figure 16b for 2024 aluminium. Reading off the pessimistic curve, a 10 year life dictates a skin thickness of .2 cm. Furthermore, the author states that the equivalent times for steel should be increased by a factor of 10. Molybdenum is even denser than steel, so it is unlikely that perforation will ever occur during the design life of the radiator.

In the past, the classic shape of a power system's radiator consisted of many stacked radiating panels, all connected to inlet and outlet headers (see figure 17). The design made for convenient deployment, being packaged much like the solar cells on Skylab's telescope mount. Since the

Figure 16a. Freezing point of NaK vs. composition [2]

Figure 16b. Meteorite puncture rate vs. Al. skin thickness. [11]

Figure 17. 3/4 view of Brayton Space Power System showing radiator manifolding detail.

design seems like a good one, this author chose to optimize the configuration for most power radiated and minimum mass. The simplest optimization to visualize is the search for the optimum number of stacked panels that results in the least mass. If there were only one panel it would have to carry the entire heat load, would be very long and have a large wetted perimeter. Most of the mass would be tied up in the single tube carrying the coolant. If this single panel were bent into a U there would be zero manifolding mass. On the other hand, if there were hundreds of these stacked assemblies, the heat load per panel would be quite small with a correspondingly small wetted perimeter. But the manifolding mass becomes prohibitive. So an optimum number of stacked assemblies does exist. Within this optimum search there are also sub optimizations on the width and thickness of the fins, coolant Reynolds number and the length of the panels. The wetted perimeter is only a function of the number of stacked assemblies and the Reynolds number inside the pipe.

Since realistic deployment schemes and Shuttle packaging were factors in the layout of the radiators, 3 wings of stacked assemblies symmetrically arranged around the receiver cavity housing were envisioned. This analysis did not consider that some of the dissipated energy from one wing would be seen by another. For that reason 2 wings might have been better, but the packaging bulk on either side of the receiver housing may not have fit inside the cargo bay.

While carrying out the process of optimization, the

physical properties of the mass flow times the heat capacity of the cycle working fluid was matched by the coolant.

5.3 Radiator Modeling

The equations that model the heat flow in this particular case tie in the total heat lost along the tube length to the heat flow into the pipe wall and finally to the heat radiated from the fins. Mathematically this becomes

$$\dot{m} C_p \frac{dT_1}{dx} = -h_f (T_1 - T_w) p_w = -2 h \lambda \left(\frac{dT}{dy} \right)_{y=0} \quad \text{eqn.[01]}$$

where $\dot{m} C_p$ is the mass flow times the specific heat of the coolant

T_1 is the liquid temperature at the core of the pipe

T_w is the temperature of the pipe wall

h_f is the film coefficient

p_w is the wetted perimeter

h is the fin thickness

λ is the heat conductivity of the fin material

$\left(\frac{dT}{dy} \right)_{y=0}$ is the temperature gradient at the fin root

If one can assume that the ratio of the wall to the liquid temperature remains constant along the tube length or

$$T_w = b T_1 \quad \text{eqn.[02]}$$

then eqn.[01] can be rewritten as

$$\dot{m} C_p \frac{dT_1}{dx} = -h_f T_1 (1 - b) p_w$$

Check figure R3 for clarity. Integrating from 0 (the entrance to the pipe) to some distance x down the pipe, the liquid temperature at that point becomes

$$T_1 = T_1(0) \exp \left[- (1 - b) \frac{h_f p_w}{\dot{m} C_p} x \right]$$

where $T_1(0)$ is the inlet temperature, abbreviated T_{in} . We can also rewrite this equation as

$$\frac{T_1}{T_{in}} = \exp - \left[(1 - b) \frac{h_f p_w}{\dot{m} C_p} L \right] \frac{x}{L} \quad \text{eqn.[03]}$$

If the integration is carried out along the total length of the pipe, we can obtain an expression for the exit to inlet liquid temperature which can be defined as the quantity μ .

$$\frac{T_{out}}{T_{in}} = \exp - \left[(1 - b) \frac{h_f p_w}{\dot{m} C_p} L \right] = \mu$$

So then eqn.[03] can be written simply as

$$\frac{T_1}{T_{in}} = \mu^{x/L}$$

Assigning z to the dimensionless quantity x/L , the expression for the wall temperature becomes

Figure 18. Radiator panel section and panel detail comprising of 8 stacked panel assemblies.

$$T_w = b T_{in} \mu^z \quad \text{eqn. [05]}$$

On the other side of the wall, a different energy balance holds for the heat flow from the fin. Here the assumption is made that the fin conducts heat in only one dimension, away from the pipe. In reality, the problem is two dimensional, but errors introduced as a result of this assumption are reported [NN] to be virtually insignificant.

$$\frac{d}{dy} \left(h \lambda \frac{dT}{dy} \right) = \epsilon \sigma (T^4 - T_s^4) \quad \text{eqn. [06]}$$

where ϵ is the fin emissivity at the appropriate wavelength
 σ is the Stephan Boltzmann constant
 T_s is the background sink temperature, here 270 K

One boundary condition comes from eqn. [05] and the other from the fact that there can be no temperature gradient at the fin tip

$$T(0) = T_w \quad \text{and} \quad \left(\frac{dT}{dy} \right)_{y=w} = 0$$

Then the power radiated per panel becomes

$$\frac{Q}{N_s} = -2 \lambda h \int_0^L \left(\frac{dT}{dx} \right)_{y=0} dz \quad \text{eqn. [07]}$$

Furukawa [09] combined eqns. 05, 06, and 07 by the method of calculus of variations to come up with an expression that relates all the key variables to the dissipated power. His equation served as a starting point for the optimized design

of the fin and tube radiator. The equation is as follows:

$$\frac{Q}{N_s} = \frac{23 \lambda h l}{10 w} \int_0^1 \frac{\epsilon_p \sigma w^2}{\lambda h} (T_b - T_s)^4 dz \left(1 + \frac{8 \epsilon_p \sigma w^2}{5 \lambda h} T_b^3 \right)$$

where T_b is the base or wall temperature, renamed. See eqn.[05].

The program that optimizes the Brayton power system calls a radiator design subroutine with a desired dissipated power, an inlet temperature, an outlet temperature and the mass flow rate times the specific heat of the coolant. The subprogram then optimizes the radiator configuration for the minimum mass (or volume). This results in a four variable optimization for a particular design point. The variables are (l , w , h , and N_s) and the cost is volume or mass. Several constraints need to be considered: that the liquid flow within the radiator tubes remain turbulent in all sections to assure good heat transfer, and that the dissipated power is always achieved. The Reynolds number was arbitrarily picked at 4000, a number that results in barely turbulent flow. Even though higher Reynolds numbers would result in a lighter design, the pressure drop in all the passages would become too costly in terms of pumping power. Therefore, a maximum of one kilowatt was assigned for the task. The expression for the pressure drop (in Pascals) from Blasius' turbulent friction factor [10] is

$$\Delta P = 0.158 L \rho^{3/4} \mu^{1/4} d^{-5/4} V^{7/4}$$

where ρ is the coolant density

μ is the coolant viscosity

d is the pipe diameter

V is the coolant velocity in the pipe

One other variable that was affected by the choice of geometrical parameters is the film coefficient. In mks units it combines the dimensionless Nusselt number, the conductivity of the coolant and the pipe diameter to arrive at

$$h_f = 0.023 Re^{0.8} Pr^{0.33} \frac{k}{d}$$

The aforementioned cost is the total volume or mass of the radiator, comprised of the radiating panels and the manifolding. The volume of the panels is simply

$$PV = 2 N_s l w h + N_s h t l (p_w + p_i h t) \quad \text{eqn. [09]}$$

The expression for the manifolding is a bit more involved since it is tapered to save mass. First the cross sectional area in a panel is computed

$$A_W = \frac{p_w^2}{4 p_i}$$

In order to maintain a constant mass flow rate through the manifolding, the manifold area at the i^{th} section will simply be

$$MA(i) = AW_i$$

The length of a section (refer to fig R3) is

$$LS = 2w + \frac{pw}{pi} + 2ht$$

Then the total volume of the manifold becomes twice the sum of all the individual sections, since there are inlet and outlet headers

$$TMV = 2 \sum_{i=1}^{Ns} ht (4 pi MA(i)^{1/2} + pi ht) LS \quad \text{eqn. [10]}$$

The total radiator volume is then

$$TRV = PV + TMV \quad \text{eqn. [11]}$$

5.4 Optimization detail

It is fairly clear that many combinations of N_s , L , w and h will satisfy the required dissipated power. The key is to find the particular one that results in the minimum mass. Equation 8 can be thought of as the constraint equation, that is the quantity Q/N_s is always fixed within an optimization of L , w and h . The number of stacked assemblies (N_s) has to be an integer, so to remove a degree of freedom from the

computations, the optima of L, w and h can be plotted as a function of Ns. The resulting peak in the curve will be the global optimum for the design. In an abbreviated form, eqn.[108] can be recast as

$$\frac{Q}{Ns} = \text{const} = XI (Ns, L, w, h) \quad \text{eqn.[112]}$$

The equation that is being optimized (maximized) is

$$\frac{Q/Ns}{TRV} = PHI (Ns, L, w, h) \quad \text{eqn.[113]}$$

The simplest way to do this is by one variable at a time, and then repeat the procedure until some convergence criterion is met. The author recognizes that this method is inefficient, yet it is simple to implement. For example, one could start by optimizing width to length while holding the thickness h constant. Taking the differential of eqn.[112] gives

$$d \left(\frac{Q}{Ns} \right) = XI_w dw + XI_L dL = 0$$

where the subscripts mean the partial of XI with respect to w (or L). Solving for dL gives

$$dL = \frac{-XI_w}{XI_L} dw \quad \text{eqn.[114]}$$

Similarly for eqn.[113]

$$dPHI = PHI_w dw + PHI_L dL = 0$$

Or using eqn.[14]

$$d\text{PHI} = \left(\text{PHI}_w - \frac{\text{XI}_w}{\text{XI}_L} \text{PHI}_L \right) dw = 0$$

where

$$\text{PHI}_w = \frac{\text{XI}_w (\text{TRV}) - \text{XI} (\text{TRV})_w}{\text{TRV}^2}$$

and

$$\text{PHI}_L = \frac{\text{XI}_L (\text{TRV}) - \text{XI} (\text{TRV})_L}{\text{TRV}^2}$$

substituting and simplifying, one finds that the condition that needs to be met is

$$\frac{(\text{TRV})_w}{\text{XI}_w} = \frac{(\text{TRV})_L}{\text{XI}_L}$$

Notice that this ratio is just the "Lagrange multiplier" in this constrained optimization. A similar expression for a thickness optimum can be found, but methods to compute the actual answers became very time intensive. The quickest and easiest solution turned out to be that of successive one dimensional minimizations. Therefore the elegant methods were discarded. For illustration, the partial derivatives are included in appendix [A] for possible future use. The author resorted to computing the quantity represented by eqn.[13] and marching one direction at a time to the maximum, satisfying the constraint equation at every step, until the maxima converged.

5.5 Optimization Results

After all the relevant equations were coded, the

subprogram did indeed find an optimum configuration. From the thermodynamic cycle analysis, the desired dissipated power was to be 118,100 watts coming into the radiators at 673 K and exiting at 350 K. The product of coolant mass flow and specific heat was to be 408 J/sec/K. As discussed before, there are 3 wings of stacked panels. Their overall dimensions worked out to 1.7 by 11.6 meters each, consisting of 200 stacked panels in each wing. The actual mass of the assemblies was computed to 148.5 kg. The author added an arbitrary 20 per cent to that figure to account for deployment mechanisms and stiffening braces, as well as another 1.55 KG/Kwe (1.1 KG/KWt) for the waste heat exchanger. Therefore the total mass of the radiator system came out to 320 kg. The optimum fin thickness worked out to 0.016 cm., with a corresponding internal tube diameter of 0.354 cm. The power to circulate the coolant through all of the tubes was only 24 watts. The pressure drop calculation is optimistic since the pressure drops in the manifolding were not computed, nor that through the waste heat exchangers. Figure 19 shows the sensitivity of the geometrical dimensions to the number of stacked assemblies. Also note that the specific mass of these off-optimum designs do not differ from the chosen design by more than 0.07 kg/kWe, which is not too significant. Therefore one could conclude that since the radiators in this design are the lightest components of the power system, minor adjustments in configuration could be made without incurring any great

penalties.

Chapter 6. Results

Table 18 is a sample output from the program listed in the back of chapter 2. The component efficiencies and the scaling variables are the author's best estimate of current technology. The numbers are a result of an optimized search through compressor pressure ratio and cycle temperature ratio space for a minimum specific mass (KG/KWe). The two constraints on the system are 1) the top cycle temperature (1685 K), prescribed by the melting point of silicon and 2) the bottom radiator temperature (350 K), chosen for ease of radiator design (see ch. 2). As such, there is not much room for cycle temperature ratio variations and is therefore not the sensitive parameter. Compressor pressure ratio, however, suffers from no constraints and is free to float. It centers around 3.3 with an efficiency of 85%. This is well within the capability of a single stage centrifugal compressor pumping a fluid with a molecular weight of 40. The total specific mass of this system then calculates out to 28.5 KG/KWe. The contributions are 8.9 KG/KWe for the collector, 10.5 KG/KWe for the receiver (mass of silicon included), 5.5 KG/KWe for the regenerator and 3.5 KG/KWe for the radiator system. Since the compressor and turbine are made of carbon/carbon composites and are therefore very light, no attempt was made to scale the rotating group, as their contribution is well within the uncertainty of some of the other major components scaling variables.

 MDOT*CP(WATTS/DEG K) OF SYSTEM 407.1986

Traditionally, the radiators have been the most massive single components of Brayton systems. As this research began, a lot of effort was expended in modeling the radiators, to come up with an accurate estimate of mass. Therefore, there is confidence in the radiator specific mass. Here, the radiator has become the least massive component of the system. This is primarily due to the elevated operating temperatures. The system itself is a fin and tube type radiator built out of molybdenum with a mixture of sodium and potassium serving as the coolant.

Considerable effort also was expended to model the performance of the collection system, but relatively little data was available to scale the masses appropriately. Performance was quantified in terms of surface accuracy of the mirror surface (mrad) and sun pointing error. The former obviously is a function of mass, and for a zero mean, 1 mrad standard deviation surface a scaling constant of 2.1 kg/m was selected. This figure lies within the range of actual hardware, so there is also a high degree of confidence associated with the collector mass.

The receiver is the most massive component of this system, containing all of the silicon needed for heat storage during shadow periods. That alone is responsible for 4.8 KG/KWe of the receiver mass. The rest is tied up in structure, insulation and cavity temperature control. The material used for the structure is silicon carbide, some 6.5 times lighter than the refractory materials that have been

used in the past for a prototype [04]. Lurio [06] has spent considerable effort modeling the receiver, and has developed a good mass model for this component. So there is also a good degree of confidence for the receiver specific mass.

No effort was spent on properly modeling the regenerator and waste heat exchanger, as there is a large data base for existing ones. Additionally, in the early stages of this research, the cycle optimized to a high pressure ratio system, with very little regeneration needed. A more realistic assessment of the radiator design (raising the bottom radiator temperature) reversed the trend, and the cycle converged to a modest pressure ratio system with a significant amount of regeneration. The scaling variable selected for the specific mass calculation for the regenerator was 3.22 KG/KWt, derived from ref[05]. In retrospect, this figure is unnecessarily large. Reference [05] designed the unit out of refractory metals, and circulated a high molecular weight (80) working fluid through it. Later Garrett [07] designs have brought this figure down to 0.85 KG/KWt for a system circulating inert gas mixtures of 40 g/mole. Therefore, the regenerator specific mass is some 3.8 times heavier than need be.

6.2 Parametric studies

To properly identify this system's sensitivity to the choices of scaling variables and assumed efficiencies, a sensitivity analysis was conducted on all the relevant

parameters. Collector efficiency and radiator specific mass estimates were exempt from this analysis for reasons previously discussed.

Figures 20 through 25 summarize the results of the sensitivity analysis. The first quantity varied (fig. 20) is the collector scaling constant. The range spans 1.5 kg/m to 5.0 kg/m, and the nominal value was picked at 2.1 kg/m. Since the collector is already a sizable portion of the power system, this perturbation pushes the specific mass of the system from 25.9 to 40.9 KG/KWe. Overall cycle efficiency displays a slight dependance on this scaling constant going from 25.2 to 25.3, due to re-optimization at a higher pressure ratio. Right away, one can identify the need for an accurate number for this scaling constant.

Since the regenerator specific mass estimate was uncertain, its scaling constant was varied from 1 to 4 and the nominal value was chosen at 3.22 KG/KWt. The overall cycle efficiency showed little sensitivity, varying from 24.9 to 25.2 percent. The specific mass ranged from 24.8 to 29.8 KG/KWe, a significant variation, illustrating the need for a better estimate for this scaling constant.

Figure 21 relates system specific mass and overall efficiency to compressor and turbine efficiency variations. Of the two, excursions in turbine efficiency had the most impact on system performance, although not by much. Compressor efficiency was varied from 80 to 90 percent, which pushed the cycle efficiency from 23.4 to 26.7 per cent. Specific mass correspondingly went down from 30.5 to 26.9

KG/KWe. Traditionally, the turbine can achieve more efficiency in a stage than can a compressor, so the compressor efficiency was varied from 85 to 95 percent. Cycle efficiency went from 23.3 to 26.9 percent, while specific mass decreased from 31.6 to 26 KG/KWe.

Figure 22 relates in similar fashion alternator efficiency and storage efficiency to specific power and cycle efficiency. Of the two the storage efficiency, which is a measure of the quantity of insulation in the receiver, is the more sensitive parameter. It was varied from 80 to 95 percent, and pushed the cycle efficiency from 25.2 to 29.9 percent. The specific mass went from 28.5 to 24.3 KG/KWe, a significant drop. This result is a bit contrived, since there was no mass penalty for the extra insulation. The alternator efficiency also was varied from 80 to 95 percent, and similarly drove the cycle efficiency from 23.8 to 26.6 percent. The specific mass dropped from 30 to 27.2 KG/KWe.

Figure 23 illustrates the impacts of the regenerator and waste heat exchanger effectiveness on cycle efficiency and specific power. Since these units are similar in function, their effectivenesses were varied over the same range, namely from 85 to 95 percent. I discovered that the waste heat exchanger had a larger impact on system performance than the regenerator, undoubtedly due to the necessary added mass of the radiators. The waste heat exchanger variations pushed the cycle efficiencies from 24.2 to 26.2 percent and drove the specific mass levels from 30.2 to 27.1 KG/KWe. The

regenerator variations perturbed the cycle efficiencies from 24.1 to 26.5 percent and moved the specific mass levels from 29.2 to 27.9 KG/KWe.

Figure 24 shows how technology level might affect overall cycle efficiency and specific mass. Worst case is defined as taking all the above efficiencies and scaling constants that would result in the heaviest system and optimizing the resultant. Best case is the converse. The nominal technology level is what can be achieved today, and results in an overall cycle efficiency of 25.2 percent with a specific mass of 28.5 KG/KWe. The best that one can achieve is in this author's opinion, 14.4 KG/KWe and the worst would center around 60 KG/KWe.

Figure 25 shows the mass breakdowns of the components vs. the same technology level. Notice that the receiver remains a fairly constant, large fraction of the power system. Also, as the technology level increases, the regenerator becomes a less significant portion of the system mass, to the point where it might be better to neglect it entirely.

To present these results in a better light, consider that over the range of values of the perturbations, the decreasing order of impact is as follows: reflector scaling constant (15 KG/KWe), turbine efficiency (5.6 KG/KWe), regenerator scaling constant (5 KG/KWe), storage efficiency (4.2 KG/KWe), compressor efficiency (3.6 KG/KWe), waste heat exchanger effectiveness (3.1 KG/KWe), alternator efficiency (2.5 KG/KWe) and finally, regenerator effectiveness (1.3 KG/KWe). This listing should not be taken as an absolute measure of

relative importance, since the limits of the variations were somewhat arbitrarily chosen. Had different limits been chosen, the order of impact might have been different.

Chapter 7. Conclusions and recommendations

This thesis certainly has validated the concept of a high temperature solar Brayton cycle with latent heat of fusion energy storage. The power system was optimized for minimum specific mass, and converged to 28.5 KG/KWe. The corresponding cycle efficiency was 25.2 percent. The author did not consider gimballing or redundant sets of turbomachinery, which would add at least 10 KG/KWe to the system mass. Those decisions would have to be made after a more detailed study of the space station's attitude (earth or sun pointing) and reliability requirements.

However, there are still some fine points to consider. The concept of thermal storage tubes was tested by Lewis Research Center [11], albeit with different materials. Their goal was to achieve a gas working temperature of 1090 K throughout an orbital period. The gas temperature varied from 26 K above to 18 K below the nominal temperature, during simulated orbital periods. The tubes were constructed from columbium - 1% zirconium and were filled with LiF, which releases 1046 kJ/kg at 1121 K. These tubes were tested for 1251 sun - shade cycles with no real problems other than some local distortions in the outer tube convolutions. This was probably a combined effect of gravity and a 30% change in volume during the change of phase. This probably would not have occurred in 0 gravity. In short that program was successful. In my particular application, the tubes are built of silicon carbide, and the energy storage is accomplished

with silicon, which releases 1787 kJ/kg at 1685 K. Additionally, silicon undergoes only an 8 percent volume change during the change of phase. The silicon carbide ceramic is necessary because of the elevated temperature. In the first analysis the long term compatibility of silicon carbide with hot silicon should not present any problems, but there is no hard data to verify this assumption.

Another area that needs to be verified is the durability of carbon/carbon turbines at temperature and speed. Although the environment is benign with almost no thermal cycling, these turbines are still experimental. As stated earlier, they have been tested to 2200 K and to 720 m/s. These results [12] are encouraging, but definitive design data is not yet available.

The alternator, even with an assumed efficiency of 90%, is going to produce 10KW of heat for an electrical output of 90 KWe. Therefore, alternator cooling cannot be ignored. Injecting cooled gasses (He) in the alternator housing is a solution, but windage losses could become significant. The mass of this other cooling system would then have to be accounted for. Since all of the machinery rotates on a common shaft, another solution could be envisioned. Heat pipes could be routed from the windings through the hollow shaft, through the compressor face, and ultimately sink their heat load into the incoming compressor stream. Careful design would have to insure that the vapor pressure at the evaporator could overcome the local centrifugal force, but this same force would assist in the return of the condensed vapor through the

wick. If this could prove possible, then the alternator could spin in vacuum, reducing the windage losses to zero. The peak cycle pressure is only 1.25 atmospheres, so the sealing requirements aren't severe. Naturally, the system would have to be re-optimized for a compressor inlet temperature that would be some 25 K warmer.

Another pivotal topic is the seals that isolate the compressor and turbine from the alternator. These seals should have no problem dealing with the pressures in the rotating machinery. But their design would have to minimize leaks over a ten year life at very high temperatures. No attempt was made to look into this subject, but it needs to be addressed if this concept is ever taken to a more complete design.

Unfortunately, the capability of achieving at least a half of a degree pointing accuracy for the collector needs to be looked at more seriously. This concern ties in with the rest of the design of the space platform. Docking perturbations, shifting masses and the quality of the attitude control all affect the pointing accuracy requirement. There also will be some continuous expenditure of energy in one form or another to meet this criterion. The complete impact of this concern needs further research.

The subject of mirror surface quality degradation quickly was analysed in chapter 3. The conclusion there was that a thin coating of quartz might have to be applied to the mirror surface to protect it from free oxygen in low earth

orbits. If this system is used to power a low thrust orbital transfer vehicle that operates between LEO and GEO, it will have to traverse the Van Allen radiation belts. It is questionable to assume that the mirror will be unaffected by high energy protons. Either a laboratory experiment or a flight test might have to be conducted to fully quantify this effect.

As discussed earlier, the radiators are constructed out of molybdenum and circulate a coolant composed of sodium and potassium. The solubility of molybdenum in hot NaK [3] also needs to be checked and evaluated over a mission lifetime. If it should prove unacceptable, some other material will have to be chosen (stainless steel) for the tube and fin material, and the radiators redesigned. Stainless is a worse conductor of heat, so the radiator mass would have to increase.

In general, the high temperature solar Brayton space power system is a simple, reliable concept that does not suffer from insurmountable technological difficulties. All of the potential problems addressed above can be solved with a minimum of effort along with a better understanding of the power system's integration with the larger system. The author feels that this system has a definite niche in the power options being considered for the 1990's.

Appendix A

This appendix lists the various partial derivatives of equation 8 in section 6.3 that are used in any optimization algorithm. One can start by recasting equation 8 with a change of variables. Let

$$g = \frac{\text{em sig } w^2}{h \text{ lamb}}$$

Then equation 8 becomes

$$\frac{Q}{Ns} = \frac{23 \text{ lamb } h}{10 w} \int_0^1 \frac{g (Tb^4 - Ts^4)}{1 + \frac{8}{5} g Tb^3} dz$$

Can start by computing $d(Q/Ns)/dw$: For clarity, the operation is shown in pieces.

$$\begin{aligned} \frac{d(Q/Ns)}{dw} &= \frac{23 \text{ lamb } h}{10 w} \frac{d}{dw} \int_0^1 \frac{g (Tb^4 - Ts^4)}{1 + \frac{8}{5} g Tb^3} dz \\ &+ \int_0^1 \frac{g (Tb^4 - Ts^4)}{1 + \frac{8}{5} g Tb^3} dz \frac{d}{dw} \left(\frac{23 \text{ lamb } h}{10 w} \right) \end{aligned}$$

The derivative of the integral becomes

$$\int_0^1 \frac{2 g (Tb^4 - Ts^4)}{w (1 + \frac{8}{5} g Tb^3)} - \frac{16 g^2 Tb^3 (Tb^4 - Ts^4)}{5 w (1 + \frac{8}{5} g Tb^3)^2} dz$$

Or simplifying,

$$\int_0^1 \frac{g (T_b^4 - T_s^4)}{1 + \frac{8}{5} g T_b^3} \left\{ \frac{2}{w} - \frac{16 g T_b^3}{5 w (1 + \frac{8}{5} g T_b^3)} \right\} dz$$

Additionally, the derivative of the first part of [A2] is

$$- \frac{23 \text{ lamb } h \text{ l}}{10 w^2}$$

Rewriting [A2] in terms of [A3] and [A4]

$$\begin{aligned} & \frac{23 \text{ lamb } h \text{ l}}{10 w} \int_0^1 \frac{g (T_b^4 - T_s^4)}{1 + \frac{8}{5} g T_b^3} \left\{ \frac{2}{w} - \frac{16 g T_b^3}{5 w (1 + \frac{8}{5} g T_b^3)} \right\} dz \\ & - \frac{23 \text{ lamb } h \text{ l}}{10 w^2} \int_0^1 \frac{g (T_b^4 - T_s^4)}{1 + \frac{8}{5} g T_b^3} dz \end{aligned}$$

This last equation can be simplified one step further. So the equation for $d(Q/N_s)/dw$ becomes

$$\frac{23 \text{ lamb } h \text{ l}}{10 w} \int_0^1 \frac{g (T_b^4 - T_s^4)}{1 + \frac{8}{5} g T_b^3} \left\{ \frac{1}{w} - \frac{16 g T_b^3}{5 w (1 + \frac{8}{5} g T_b^3)} \right\} dz$$

Next on the list to figure is $d(Q/N_s)/dl$. This derivative is a bit more involved since [A1] is being integrated over a

normalized length. As before,

$$\begin{aligned} \frac{d(Q/Ns)}{dl} &= \frac{23 \text{ lamb } h \text{ l}}{10 w} \frac{d}{dl} \left(\int_0^1 \frac{g (Tb^4 - Ts^4)}{1 + \frac{8}{5} g Tb^3} dz \right) \\ &+ \int_0^1 \frac{g (Tb^4 - Ts^4)}{1 + \frac{8}{5} g Tb^3} dz \frac{d}{dl} \left(\frac{23 \text{ lamb } h \text{ l}}{10 w} \right) \end{aligned} \quad [A6]$$

If one functionally rewrites the derivative of the integral above as

$$\frac{d}{dl} \int_0^1 f(z, l) dz \quad [A7]$$

where $z = \frac{Z}{L}$ and $dz = \frac{1}{L} dZ$

Then [A7] becomes

$$\frac{d}{dL} \int_0^L f\left(\frac{Z}{L}, L\right) \frac{1}{L} dZ$$

or

$$\int_0^L \frac{d}{dL} \left(\frac{1}{L} f\left(\frac{Z}{L}, L\right) \right) dZ + \frac{1}{L} f(1, L) \quad [A8]$$

Expanding the term inside the integral one obtains

$$-\frac{1}{L^2} f(z) - \frac{1}{L} \left(\frac{\partial f(z)}{\partial Z} \right) \frac{Z}{L} + \frac{1}{L} \left(\frac{\partial f(z)}{\partial L} \right) \frac{Z}{L}$$

The subscript next to the partials indicates which variable

is treated as a constant. Carrying out the integration one obtains

$$-\frac{1}{L} \int_0^1 f(z) dz = -\frac{1}{L} \int_0^1 \left(\frac{f(z)}{z} \right) z dz + \frac{1}{L} \int_0^1 \left(\frac{\partial f(z)}{\partial L} \right) \frac{z}{L} dz$$

Substituting this expression into [A8] will transform [A7] into the proper form of

$$\int_0^1 \left(\frac{\partial f(z)}{\partial L} \right) \frac{z}{L} dz \quad [A9]$$

Substituting in all the proper variables for [A9], one gets

$$\int_0^1 \frac{\mu C_p \dot{m} \log(\mu)}{h f L^2 p w \log(10)} \left\{ \frac{24/5 g^2 T_b^2 (T_b - T_s)^4}{1 + \frac{8}{5} g T_b^3} - 4 g T_b^3 \right\} dz \quad [A10]$$

Note that this last expression only takes care of the first line of [A6]. The last derivative of [A1] that needs to be found is $d(Q/N_s)/dh$. Eliminating the lengthy algebra, one arrives at

$$\frac{23 \lambda h l}{10} \int_0^1 \frac{g (T_b - T_s)^4}{1 + \frac{8}{5} g T_b^3} \cdot \frac{8 g T_b^3}{5 h (1 + \frac{8}{5} g T_b^3)} dz \quad [A11]$$

To complete the analysis, the same sequence of derivatives is needed for eqn.[11] in section 6.3, which is the expression for the total radiator volume. These are quite simply

$$\frac{d}{dw}(\text{TRV}) = 2 N_s L h + 4 \sum_{i=1}^{N_s} h t (p w^{1/2}(i) + h t p_i)$$

$$\frac{d}{dL}(\text{TRV}) = 2 N_s w h + N_s h t (p w + h t p_i)$$

$$\frac{d}{dh}(\text{TRV}) = 2 N_s L w$$
